# DISCRIMINANT FUNCTION ANALYSIS AS A POST - HOC OPERATIONS RESEARCH DETERMINANT OF CRITERION STRENGTH AND BINARY DECISIONING RELIABILITY

Dr. Brent E. Wholeben University of Texas at El Paso University of Washington

Portions of this study were performed pursuant to a grant from the National Institute of Education, and the Northwest Regional Educational Laboratory. Views presented are those of the author; and no endorsement from either granting institution should be inferred.

#### INTRODUCTION TO THE STUDY

This investigation sought to evaluate the utility of discriminant functions and their related statistics, in providing a practical post-hoc determinant of criterion strength and decisioning (sic) reliability for decision-making in the multiple alternatives environment (Wholeben, 1980a). Past experience with the use of binary integer programming (operations research) models in the selection of elementary school sites for closure during severe enrollment decline had demonstrated, that discriminant functions could provide a useful tool to the decision modeler -- not only to assist an evaluation of the model's reliability in constructing various solution set vectors (i.e. the schools to be closed versus those to remain open) in the form:

#### [100111000...0]

where 1=open and 0=close; but also to provide an accountability framework for the public's understanding of the methodology utilized and the reasonableness of

Presented at AERA 1982, MLR Special Interest Group Not refereed by editorial staff the results (solutions) according to the criterion references employed. This current paper seeks to expand upon that 1979 investigation, and provide additional data supporting the use of discriminant functions as an effective post-hoc technique for evaluating not only decisioning reliability but also the relative impact which each of the applied criterion references provided to the construction of the resulting decision (solution set vector formulation).

This paper will proceed to <u>first</u> acquaint the reader briefly with the idea of multiple alternatives modeling (MAM), and present a strong rationale for evaluating and simulating potential alternative decisions via an easily constructable criterion-referenced methodology. <u>Secondly</u>, the reader will be introduced to the "tools" of the MAM evaluator, and the rudiments of a nomenclature which will be utilized within the body of this report. <u>Next</u>, the findings of the 1979 school closure model (SCHCLO) will be summarized as an indication of the utility of discriminant functions in assessing decisioning model reliability for the "complete" matrix model case -- that is, a criterion model with <u>no</u> empty cells due to missing or incomplete (irrelevant) data entries. <u>Finally</u>, the use of discriminant functions for assessing modeling reliability and individual criterion strength associated with each decision will be studied, utilizing the 1981 fiscal deallocation model (ROLBAK) for evaluating budgeting unit alternatives for deallocation during funding roll-backs; and emphasizing the "scant" matrix model case.

The objective of this paper remains to demonstrate the utility of discriminant functions in assessing the relationship between those criterion references designated as providing the rationale underlying the decisions made; that is, to correlate decision sets (solution vectors) with the criteria, and thus measure the relationship of criterion variance in the prediction of solution vector membership. Furthermore as an auxillary objective, the use of discriminant functions will also provide a useful 'at-hand' technique for understanding the weighted value (or strength) for each of the criterion referenced variables entered into the discriminant function formulation. Finally, these results will demonstrate the utility of discriminant functions in the assessment of decisioning reliability and criterion strength for both the "complete" and "scant" criterion matrix of values.

# CRITERION STRENGTH AND DECISIONING RELIABILITY

Evaluation and all decision-making resulting therewith, demand a high degree of accountability, visibility and responsibility. Today's complex issues require equally complex methodologies to assess both content and process of such issues, and to provide an understandable environment within which to simulate potential decisions and measure resulting effect or impact. As important moreover, is the secondary demand for providing a means for post-hoc evaluating not only the results of the simulated decisions, but also the influence (singularly as well as collectively) which the criterion references lend in making the original decisions. The clear need for the criterion-referenced decision-maker therefore is to satisfy the following five objectives:

- [1] to <u>validate</u> the sophisticated decisioning methodologies which are so necessary for addressing today's complex problems -- yet so often ignored, discounted or feared;
- [2] to <u>study</u> criterion effect upon the decisions made, and the <u>impact</u> which the system receives via those decisions; and thereby understand differential criterion weighting and influence -- "what" made a difference in constructing the decisions, and the varying impact resulting;
- [3] to provide a high degree of visibility, and therefore accountability, to the public interests served and affected via those decisions -- generating a milieu of trust within which the decisions, no matter how unexpected, can be trusted and accepted;
- [4] to <u>simulate</u> the variable impact upon the decisions made by introducing additional criterion influences into the model, and thereby perform a path analysis from solution to solution as different criteria are utilized to construct each decision or solution -- satisfying the innate need of some individuals who must always ask, "... but, what if ...?"; and

[5] to <u>permit</u> easy and quick decisioning replication within an ever changing environment -- knowing the relationships between past successful decisions and the criteria used to construct those solutions, in order to understand the potential of future decisions based upon the new values of more current criterion measures.

This paper demonstrates the superlative ability of a parametrically-based, statistical technique to satisfy each of the five objectives stated above. Relying upon multivariate, linear regression techniques, DISCRIMINANT FUNCTIONS, constructed to relate criterion vectors to a singular 'solution set vector' containing either a binary (1,0) decision representation or the composite entries of a 'selection tally vector' (0,1,2,3,...), provide the basis upon which the required measures of criterion strength and decisioning reliability will be constructed.

Generally, the notion of <u>criterion strength</u> refers to the identification of those measures which in effect constructed the final decision or solution to the modeled problem; and furthermore provide a 'factor' measure of ordinal value or weight within that same group of 'solution-formation' variable measures. Specifically, criterion strength will address <u>three</u> fundamental questions existent within all decisioning evaluation:

- [1] which criterion references most clearly defend the decisions made?
- [2] to what extent are the criteria individually representative of the decisions made?
- [3] how do the most discriminating criteria within this decision setting relate to each other in terms of importance and influence?.

This paper will illustrate the utility of discriminant function(s) formulation for answering these questions of <u>criterion strength</u>, respectively, by evaluating the following rudiments of discriminant analysis:

- [1] criteria included within the formation of discriminant functions
   -- that is, which references were 'entered' into the composition
   of the prepared functions;
- [2] order-of-entry of each of the variables which discriminate the final solution vector; and
- [3] weight (or factor strength) relationship between the standardized canonical discriminant coefficients.

Generally, the notion of <u>decisioning reliability</u> refers to the degree of trust which is implicit to the decision model (in this case, the "multiple alternatives model" - MAM); implicit in the sense, that the decision-maker can accept the results of such a criterion-referenced technology, both in terms of content (<u>viz</u>., effect of the criterion references within the model) as well as process (<u>viz</u>., effect of the model upon the criterion references). Specifically, decisioning reliability will address <u>two</u> fundamental questions existent within all decisioning evaluation:

- [1] to what extent are the criteria collectively representative of the decisions made?
- [2] to what extent can the defined matrix of criterion references re-predict the original binary (include v. exclude) solution?.

This paper will illustrate the utility of discriminant function(s) formulation for answering these questions of <u>decisioning</u> <u>reliability</u>, respectively, by evaluating the following charactistics of discriminant analysis:

[1] canonical correlation coefficients which offer a measure of relationship between the 'set' of discriminating criterion references and the 'set' of dummy variables which are used to represent the solution vector; and

[2] the frequency of mis-inclusions and/or mis-exclusions (or over-estimations and/or under-estimations) discovered when the classification coefficients constructed to predict a solution with the known relationships among the discriminating criteria variables, are utilized to repredict the original dependent variable (original solution).

# DESIGN OF THE MULTIPLE ALTERNATIVES MODELING (MAM) FORMULATION

The complex issue of multiple alternatives decision-making is no stranger to the educational analyst. The selection of some number of schools from a relatively large pool of potential candidates for closure is a MAM problem. site represents varying measures of effectiveness, efficiency, satisfaction and expenditure for each of a number of criterion references (e.g. capacity of building, heating requirements, building age, projected enrollment change over future years, safety factors of neighborhood, and proximity of other schools and their ability to absorb transferees in the event of the first school's closure). Some of these measures will be adjudged satisfactory (or nonsatisfactory) to varying degrees, and will be comparable with other schools across the district. However, to include one site for closure as opposed to another site means, that "good" aspects of a 'to-be-closed' school must be sacrificed in order to keep the other school operational, even though the 'to-be-kept-open' school may have certain unsatisfactory measures on the same criterion variables which the now closed school exhibited as satisfactory. Such modeling of this decisioning situation is known as interactive effects modeling (Wholeben, 1980a), and represents the necessity of constructing solutions sets which will invariably include some form of 'controlled' preference/trade-off mechanics as the various alternatives are evaluated. The issue of complexity is also represented in the statement of the problem: to select some number of schools for closure in order to promote certain defined goals of the district; and thus to determine how many schools will be closed and which ones. Obviously, such a model must in effect be simultaneously performing these two inter-related decisions: "how many?" and "which ones?".

The determination of which program unit budgets will be decisioned for continued funding (versus deallocation) is another example of the multiple alternatives framework, and its superior contribution to the realm of accountable and criterion-referenced evaluation and decision-making (Wholeben and Sullivan, 1981). In the fiscal deallocation model, criteria represent the projected expenditures within each object cost code for each of the units under evaluation; and in addition contain perceptual measures of administrative level of expendability. Once again of course, exists the dual responsibilities for determining how many program budgets will be discontinued, and which ones -- based upon the interactive modeling effects of the various criterion weights across unit alternatives.

The multiple alternatives model is simply a system of simultaneous linear inequalities and equalities which collectively represents the problem to be solved. Such an algebraic linear system is portrayed in *(Figure 1)*. Note how each linear combination represents a vector of values (viz., coefficients) which identifies the total, measureable impact to a system of the alternatives being modeled. Thus there exists a unique (normally) combination of coefficients for each of the criterion references used as input to the decisioning process. The alternatives themselves are further defined as binary variables (that is, taking on the value of either 0 or 1 (to be excluded in the final solution set, or to be included, respectively). Vector formulation for each criterion reference,

# [ ai1x1 ai2x2 ai3x3 ... aijxj ]

bortraying <u>i</u> criterion references across <u>j</u> alternatives, will then provide a basis for measuring total impact to the system as a whole attributable to the solution set constructed. Bounds (or limits) to what is allowable as a total impact to the system are expressed as vector entries within the conditional vector (or normally named, RHS, the right-hand-side). The RHS-values are the constants of the equations and inequalities modeling the system. (Figure 2) presents a listing of the four generic types of criteria to which each model should address content validity; and (Figure 3) depicts these criterion entries a members of the modeling framework previously illustrated within Figure 1.

he remainder of the modeling process concerns the use of an additional vector

to assist in determining from the potentially hundreds (or millions, in some exercises) of possible alternatives, that <u>one</u>, <u>best</u> mix for which the best, possible solution exists. This process is called the search for optimality, and the vector is known as the objective function (or sometimes, the cost vector). Geometrically, the objective function is a n-1 dimensional figure passing through the n-tuple space (convex) which is feasible (that is, includes all of the constraints postulated through the use of the linear equalities and inequalities) and which seeks a minimum point within the feasible region (if the goal is to minimize the impact of the objective function's values upon the system) or a maximum point within the feasible region (if the goal is to maximize the defined objective function's impact to the system as a whole).

Simply stated, the multiple alternatives model is a technique which seeks to construct a solution set (a vector of 1's and 0's), such that this same solution vector represents the solution of the simultaneous system, constrained by a series of competing criterion measures (vectors), and based upon the optimality demands of the objective function. Figure 1.

#### TOOLS OF THE MULTIPLE ALTERNATIVES MODELING MAM FORMULATION

To construct discriminant functions from the relationships between the model just discussed above and the resulting solutions formulated, require the use of linear vectors and combinations of vectors (matrix). Only those vector and matrix formulations most germane to this paper will be discussed below. The reader is invited to be patient until the scheduled publication of the manuscript, "Multiple Alternatives Analysis for Educational Evaluation and Decision-Making" in late summer of 1982, for a detailed illustration of all vectors and matrice pertinent to MAM.

<u>Solution</u> <u>Set Vector</u>. In order to distinguish between alternatives included or excluded as members of the final solution to the system modeled, a vector of binary-decision representations is required, in the form:

101100000...1

where '1' means that the criterion values associated with that particular x(j) will be computed to measure resulting system impact; and '0' means that the underlying criterion values will have no impact upon the system.

<u>Selection Tally Vector</u>. To observe the effect of each criterion reference upon construction of the system solution, a method called cyclic optimization (Wholeben, 1980a; Wholeben and Sullivan, 1981) is used. Under this regimen, the model is executed once for each unique criterion being used to constrain the model, where each unique criterion is cycled through the model as the objective function. For example, during one execution in the case of the school closure model, the intent may be be prepare a solution set whereby existing capacity of the remaining schools will be maximized; in another cycle, the model will be executed such that the schools remaining open within the district will minimize the amount of energy expended for facility heating requirements. The selection tally vector is basically a frequency summation vector, compiling the number of times each alternative was chosen as part of the solution vector, across all cyclic optimizations. Such a vector will be represented as:

#### **[** 3 7 0 2 0 1 ... 4 **]**

showing that the first alternative was selected as solution a total of  $\underline{3}$  times, the second alternative a total of  $\underline{7}$  times, and so forth. This vector is extremely important when the MAM procedure requires a step-wise decisioning process such as the school closure model -- evaluating a revised database after closing a single school such that the effects of closing each individual site is summarily incorporated into the next decision for determining additional site closures.

<u>Discriminant Criterion Inclusion Vector</u>. This vector simply represents another binary entry vector of 1's and 0's, signifying which particular criterion references were utilized via discriminant functions to develop the canonical classification coefficients, and the standardized canonical discriminant function coefficients.

<u>Discriminant Criterion Entry Vector</u>. This vector contains 1,2,...,k entries, where <u>k</u> criteria were utilized in the development of the discriminant functions, and the 1,2,...,k entries represent their order of entry into the discriminant formulation. Criterion variables not entered into the function(s) receive a value of '0', by convention.

<u>Discriminant Weighting Summary Vector</u>. Applying discriminant procedures to the binary solution vectors will result in the computation of standardized canonical discriminant function coefficients. These coefficients will reflect the utility of entered criterion vectors if those vectors contain standardized measures in lieu of the normal raw scores. By dividing each of the standardized canonical coefficients by the smallest of the standardized canonicals, the quotient will provide a factor of importance for each of the criteria as relative to the other criterion entered in the discriminant formulation. The discriminant weighting summary vector is a linear representation of these factors (quotients), where the minimum entry value is always '1.00' (smallest standardized coefficient divided by itself). Non-entered criterion locations receive a value of '0.00' by convention.

Other 'tools' have been referenced in the proceeding section of this paper: criterion constraint matrix, condition limits vector (RHS), objective function vector, and the cyclic optimization tracking matrix. Other formulations are currently under study by the author (e.g. the optimality weighting matrix) to investigate new relationships which may allow greater accountability and useful reliability of the multiple alternatives modeling framework.

#### THE "COMPLETE" MATRIX CASE: THE SCHOOL CLOSURE MODEL (SCHCLO)

A total of  $\underline{32}$  elementary school sites were measured across  $\underline{24}$  relatively independent criteria, resulting from previous factor analyses of an original set of  $\underline{64}$  criterion references. The criteria chosen were utilized by the multiple alternatives model for school closures (SCHCLO; Wholeben, 1980a) to evaluate the population of sites for some set of defined closures based upon the characteristics of the data; and the needs of the school district involved. Because the criteria utilized portrayed different value orientations (i.e., positive effects to be maximized; or negative effects to be minimized), the model consisted of a total of <u>18</u> cyclic MAXIMIZATIONS, and <u>6</u> cyclic MINIMIZATIONS -- for the total <u>24</u> optimizations required. The strategy was to operationalize the cyclic model, evaluate the full <u>N=32</u> sites, analyze the selection tally results, choose a single site for closure, update the database to signify the closure, and then re-evaluate the now reduced N=<u>31</u> site model for an additional closure. This step-wise closure strategy was considered consistent with the pragmatic reality of deciding school closures due to severe enrollment declines.

{Figure 4> displays the results ("tracking matrix") of the <u>N=32</u> cyclic optimization; and in addition, the selection tally vector entries (right column vector). The asterisked (\*) vector entries signify those sites considered having the most potential for closure, due to the selection tally entries. These <u>4</u> sites were simulated 'closed' (i.e. included as '0' in the solution set vector); and a stepwise <u>discriminant function analysis</u> performed to analyze the relationship between the <u>24</u>-vector criterion matrix which purportedly constructed the solution set, and the solution set thus constructed.

**K**Figure 5> displays the results of the <u>N=32</u> discriminant analysis. The single discriminant function constructed required a total of <u>8</u> criterion vectors to adequately explained the variance found within the binary solution set of 4-<u>0</u>'s and 28-<u>1</u>'s. The group-correlative relationship between these <u>8</u> criteria and the dummy variables formed by the solution set vector, was a canonical of <u>.8512</u>, explaining <u>72.5</u> percent of the variance between the criterion and solution sets. Based upon the re-classification coefficients formed, the discriminant function

was able to re-predict group membership for the solution vector (inclusion v. exclusion) with 100.0 percent accuracy.

(Figure 6) illustrates the results of the discriminant analysis to evaluate the compositional relation between the selection tally vector and the full criterion database. For convenience, any selection frequency  $\geq 5$  was entered into the discriminant model as a frequency = 5. This was considered necessary in order to provide some control over problems associated with singular frequency tally entries, and a loss therefore of variance potential. To explain the variance existent within the selection tally vector (0,1,...,5), a total of <u>16</u> criterion vectors were entered into the final construction of <u>5</u> independent discriminant functions. Re-prediction of the original vector entries proceeded with <u>100.0</u> accuracy.

Upon the choice of a single school site for closure (j=17), since tally entry = 7), the database was updated to reflect a N=31 base, and the net effect of the student transfers from the closed site. The model was re-executed, and a new tracking matrix constructed, as displayed in **(**Figure 7). A total of <u>4</u> new sites were now simulated as closed (with tally entries <u>></u> 4); and the discriminant model re-run.

(Figure 8) displays the discriminant results of analyzing the N=31 solution set. A total of 10 criteria were required to explained the independent variance -two more than the N=32 analysis. The canonical correlation existed at .8392, or 70.5 percent explained (independent) variance. Re-classification resulted in a 100.0 percent accuracy level. As before, the selection tally vector for the N=31 case was analyzed by discriminant functions; and these results are illustrated in (Figure 9). A total of 4 functions were constructed; and a re-prediction of 87.1 percent accuracy achieved. Within the re-classification, 7 occurrences of 'over-estimation' resulted (viz., an 'expected' tally entry greater than the original 'observed' value); and 1 occurrence of 'under-estimation' (viz., an 'expected' tally entry lesser than the original 'observed' value). Thus, it would seem that reclassification errored on the non-conservative side.

#### THE "SCANT" MATRIX CASE: THE FISCAL DEALLOCATION MODEL (ROLBAK)

A total of <u>31</u> program budgeting (unit) alternatives were evaluated for defunding across a total of <u>10</u> competing criterion references. In lieu of a step-wise procedure as represented in the school closure modeling framework, the model is further constrained to choose those programs for refunding such that the new operating district budget is not less than <u>675,000</u> dollars, but not more than <u>700,000</u> dollars for the particular programs under scrutiny. To study the effect of the model's solution generation process, the feasibility region as defined by the constraint matrix and the RHS-values is constructed in two distinct patterns: a highly <u>restricted</u> region in which very stringent controls are defined for the modeling procedure; and a relatively <u>relaxed</u> region in which less stringent controls are modeled. In addition, the ROLBAK formulation is executed both for cyclic maximization of the objective functions, and for cyclic matrice containing <u>10</u> potential solution sets (each) result.

This particular modeling application represents the "scant" matrix case, in that a high proportion (48.7 percent) of criterion matrix cells contained a 'zero' entry, signifying no cost for that particular alternative within a specific object-expenditure category. For the SCHCLO model, the criterion matrix was "complete" -- all cells contained a value greater than zero.

Under the 'restricted' formulation, the <u>17</u> resulting solution sets signify only <u>2</u> distinct solution vectors. In contrast under the 'relaxed' formulation, a total of <u>17</u> distinct solution vectors result. Under both restricted and relaxed limitations, <u>3</u> objective functions were unable to declare optimality due to the inability to find an initial integer-feasible solution.

{Figure 10> and {Figure 11> display the solution sets resulting from optimization
within the restricted region environments. The selection tally vector is noted,
as well as the impact upon the total budget based upon the simulated cuts (i.e.,
where X=funded). As can be easily seen, the solutions resulting from optimization
within the restricted environment present only two distinct alternatives for
later discriminant analyses.

Effect Upon Budget Deallocation Decisions Based Upon the Variable Flows of a Cyclic Objective Function, and the Interaction of a "Maximized, Restricted" Constraint Iterative Problem.

Effect Upon Budget Deallocation Decisions Based Upon the Variable Forms of a Cyclic Objective Function, and the Interaction of a "Minimized, Restricted" Constraint Interative Problem.

Figure 11.

Note: Total Initial Budget = <u>893.5</u> (\$1000's)

.

**(Figure 12)** and **(Figure 13)** display those solution sets resulting from the optimizations within a <u>relaxed</u> environment. A total of <u>17</u> distinct solution set vectors are formed; and thus the selection tally matrix demonstrates greater variability than existent within the restricted orientation.

Discriminant functions were computed for the <u>relaxed</u> modeling setting first, requiring a separate discriminant execution for each of the distinct solution vectors resulting from the MAM analysis. As noted in an earlier section to this paper, criterion strength was evaluated utilizing the three composites vectors:

#### DISCRIMINANT CRITERION INCLUSION VECTOR

#### DISCRIMINANT CRITERION ENTRY VECTOR

#### DISCRIMINANT WEIGHTING SUMMARY VECTOR.

The first vector is composed of binary (1,0) entries signifying whether a specific criterion was entered into the discriminant analysis for explaining the variance within the solution set. The second vector contains entries of  $1,2,3,\ldots$ , such that the order-of-entry for the discriminant criteria is represented. Finally, the third vector contains a factor-weight entry for each of the 'entered' vectors, to measure the relative importance of each of the discriminating criterion references.

The notion of decisioning reliability was evaluated utilizing two techniques:

#### CANONICAL CORRELATION

#### **RE-CLASSIFICATION ANALYSIS.**

{Figure 14> contains the discriminant results for solutions accountable to maximization within a relaxed region. The first ten columns contain the information from the discriminant analyses for each of the ten simulated solution sets. The ordinal numerals represent order-of-entry, while the bracketed entries

Effect Upon Budget Oeallocation Decisions Based Upon the Variable Flows of a Cyclic Objective Function, and the Interaction of a "Maximized, Relaxed" Constraint Iterative Problem.

Constraints:

Objective = <u>Maximization</u>

Effect Upon Budget Deallocation Decisions Based Upon the Variable Flows of a Cyclic Objective. Function, and the Interaction of a "Hinimized, Relaxed" Constraint Iterative Problem.

ι.

Note: Total Initial Budget = <u>893.5</u> (\$1000's)

[x.xx] contain the factor-weights computed from dividing each of the standardized anonical discriminant coefficients by the smallest such coefficient for each iscriminant analysis. For example in the first column signifying the results of discriminating the solution computed from maximizing 'certificated salaries', criteria were required to explain available variance within the solution set. The criterion 'budgetary composites' was entered first, and represents a factor of 2.51 in its importance to the remaining 4 criterion discriminants. The triterion 'certificated salaries' was entered secondly, and represents a factor of 3.17 in its relative importance for discriminating the solution set being analyzed; and so forth. The selection tally vector is similarly analyzed via discriminant functions.

For understanding the dimension of decisioning reliability, computed canonical correlation coefficients existed as follows, for <u>maximized-relaxed</u> solutions:

| Objective | Canonical   | Percent Variance | Relative              |
|-----------|-------------|------------------|-----------------------|
| Function  | Coefficient | Explained        | Rank                  |
| CERT      | .9056       | 82.0             | 3                     |
| CLAS      | .8633       | 74.5             | 6                     |
| BENE      | .8729       | 76.2             | 4                     |
| SUPL      | .9077       | 82.4             | 2                     |
| INST      | .9339       | 87.2             | 1                     |
| CONT      | .8679       | 75.3             | <b>5</b> <sup>+</sup> |
| TRAV      | .8614       | 74.2             | 7                     |
| CAPI      | .8419       | 70.9             | 8                     |
| PERC      | .7870       | 61.9             | 9                     |
| COMP      | .7281       | 53.0             | 10.                   |

Thus it would seem, that a formalized objective of "maximizing" the expenditures associated with instructional materials in determining which programs to refund during a period of scant resourses, produced the highest correlation between the criterion matrix of  $\underline{10}$  vectors and the proposed solution set vector constructed from the MAM analysis execution. Likewise, the maximization of

\* (No integer-feasible solution possible; Optimality not achieved)

'budgetary composites' produced the lowest correlation, explaining only 53.0 percent of independent variance within the MAM solution vector.

The second 'phase' of measuring decisioning reliability exists in the accuracy of re-predicting solution set membership based upon the classification function coefficients generated via the discriminant analysis. The bottom portion of figure 14 portrays these results for each of the <u>10</u> solution vectors formed by the varying criterion focus of the objective function. The results of e-classification for the selection tally vector are also displayed.

Figure 15> illustrates the similar results from applying discriminant function nalyses to the solution vectors formed by <u>minimization</u> within a <u>relaxed</u> setting he three vectors for denoting criterion strength are easily distinguishable rom the <u>7</u> successful (columns) optimizations. The re-classification portion of easuring decisioning reliability is also shown.

e computed canonical correlation coefficients for <u>minimized-relaxed</u> solutions:

#### SUMMARY OF FINDINGS

The use of discriminant functions in providing a useful post-hoc evaluation strategy for multiple alternatives decision-making has been studied within two separate real-world settings: the closure of schools; and the deallocation of program unit budgetary items. Two generalized issues of content and process were the main foci: <u>content</u>, in as much as there is a need to relate criteria used to the decisions made; and <u>process</u>, in order to verify the reliability of the decisioning procedures based upon the criteria utilized.

The author maintains, that two related "abilities" are necessary for prudent and trustworthy decision-making. The <u>first</u> ability refers to that knowledge which clarifies (1) which criteria 'effected' the decisions, and to what extent; and (2) to what degree did this 'effect' vary across the results of the cyclical optimizations. The <u>second</u> ability relates the need to study (1) the relationship between the 'optimizing vector' (objective function) and the results of a discriminant analysis; and (2) the relationship between the extent of feasibility region constraint (relaxed v. restricted) and the results of a discriminant analysis. To accomplish these ends, the multiple linear regression technique, discriminant functions analysis, is utilized to measure the topics of <u>criterion</u> strength and decisioning reliability.

The results of these discriminant analyses illustrate the superior efficacy found in relating multiple correlational strategies to discovering relationships between solution vectors and the criterion vectors (matrice) supporting those decisions. Three measures of criterion strength and two measures of decisioning reliability are illustrated for the reader -- all measures normally products of discriminant function(s) formulation.

It is a fundamental by-product of this study though all to important not to note, that the formation of "classification coefficients" within the discriminant process provides an excellent way of <u>projecting</u> expected impact from a newly collected set of data variables. By utilizing the linear combinations of this new data, 'expected correlative' decisions can be computed which maintain the

same variance relationship as the decisions utilized originally in the initial discriminant analyses.

In summary, the use of discriminant functions in addressing the issues of criterion strength and decisioning reliability has been illustrated to hold great promise for the decision-maker, evaluator and otherwise problem-solver. Increased accountability, visibility and responsibility are the maximized ends.
